Template for Reporting Results of Biomarker Testing of Specimens From Patients With Non-Small Cell Carcinoma of the Lung

Version: Lungbiomarker 1.3.0.2  Protocol Posting Date: June 2016

Completion of the template is the responsibility of the laboratory performing the biomarker testing and/or providing the interpretation. When both testing and interpretation are performed elsewhere (eg, a reference laboratory), synoptic reporting of the results by the laboratory submitting the tissue for testing is also encouraged to ensure that all information is included in the patient's medical record and thus readily available to the treating clinical team. **This template is not required for accreditation purposes.**

Summary of Changes

**Version 1.3.0.2:**
Updated notes to RET Rearrangement

**Version 1.3.0.2:**
Updated Explanatory Notes

**Version 1.3.0.1:**
Updated Explanatory Notes

**Version 1.3.0.0:**

**RESULTS**
Terminology changes (from Indeterminate to Equivocal).
Added data elements for ALK Rearrangements identified.

**METHODS**
Added Sequencing Type.
Added reporting for Anchored multiplex PCR.
Added more options for reporting MET Region.
Completion of the template is the responsibility of the laboratory performing the biomarker testing and/or providing the interpretation. When both testing and interpretation are performed elsewhere (e.g., a reference laboratory), synoptic reporting of the results by the laboratory submitting the tissue for testing is also encouraged to ensure that all information is included in the patient’s medical record and thus readily available to the treating clinical team. Use of this template is not required for accreditation purposes.

+ Cannot be determined (explain): __________________________

# EGFR activation mutation associated with response to EGFR tyrosine kinase inhibitors.
## Exon 20 EGFR activating mutations are generally associated with resistance to EGFR tyrosine kinase inhibitors such as erlotinib, afatinib, and gefitinib, although insertions at or before position 768 can be associated with sensitivity.
### The T790M mutation is typically secondary to other EGFR activating mutations and is associated with acquired resistance to tyrosine kinase inhibitor therapy. If seen in untreated/pretreated patients, may be present in the germline and indicate a hereditary cancer syndrome, in which case genetic counseling is suggested.
#### There is limited data on response to EGFR tyrosine kinase inhibitors for many of the uncommon EGFR activating mutations.

+ Data elements preceded by this symbol are not required.
**EGFR by Mutation-Specific Immunohistochemistry**
+ EGFR L858R (clone 43B2)
  + ___ Negative#
  + ___ Positive##
  + ___ Equivocal### (explain): __________________________

**EGFR Exon 19 Deletion (E746_A750del) (clone 6B6)**
+ ___ Negative#
  + ___ Positive##
  + ___ Equivocal### (explain): __________________________

# A negative result does not exclude the possibility of EGFR mutations, and testing with molecular methods should be performed if a suitable sample is available.
## Diffuse mutation-specific protein expression in tumor cells is highly correlated with EGFR mutation and as such predicts response to EGFR tyrosine kinase inhibitors.
### Tumors with faint cytoplasmic labeling should be designated as equivocal. This result can rarely occur both with and without mutation.

**ALK Rearrangement by Molecular Methods (Note C)**
+ ___ No rearrangement detected#
  + ___ Rearrangement identified##
    + ___ EML4-ALK (specify variant type, if known): __________________________
    + ___ KIF5B-ALK
    + ___ TFG-ALK
    + ___ KLC1-ALK
    + ___ Other ALK rearrangement (specify, if known): __________________________
  + ___ Cannot be determined (explain): __________________________

+ Polysomy:
  + ___ Present###
  + ___ Absent

# Absence of ALK rearrangement in cancer cells suggests that this tumor is unlikely to respond to treatment with a targeted ALK inhibitor, such as crizotinib.
## ALK rearrangement predicts response to therapy with a targeted ALK inhibitor, such as crizotinib or ceritinib. Some evidence suggests the type of FISH pattern (breakapart versus 5’ probe deletion) may have implications for treatment response and outcomes.
### Polysomy involving the ALK locus confirms that fluorescence in situ hybridization (FISH) scoring was carried out in tumor cells but does not predict response to therapy with targeted ALK inhibitors.

**ALK by Immunohistochemistry**
+ ___ Negative#
  + ___ Positive##
  + ___ Equivocal### (explain): __________________________

# Absence of ALK protein expression in cancer cells suggests that this tumor is unlikely to harbor ALK rearrangement and to respond to treatment with a targeted inhibitor, such as crizotinib and ceritinib.
## ALK protein expression in cancer cells (based on platform criteria) predicts the presence of ALK rearrangement and response to therapy with a targeted inhibitor, such as crizotinib and ceritinib.
### Tumors with faint cytoplasmic labeling should be designated as equivocal. This result can rarely occur both with and without mutation.

**ROS1 Rearrangement by Molecular Methods (Note C)**
+ ___ No rearrangement detected#
  + ___ Rearrangement identified##
  + ___ Cannot be determined (explain): __________________________

+ Data elements preceded by this symbol are not required.
+ Polysomy:
  + ___ Present###
  + ___ Absent

# Absence of ROS1 rearrangement in cancer cells suggests that this tumor is unlikely to respond to treatment with a targeted ROS1 inhibitor, such as crizotinib.

## ROS1 rearrangement predicts a high response rate to therapy with a targeted inhibitor, such as crizotinib.

### Polysomy involving the ROS1 locus confirms that fluorescence in situ hybridization (FISH) scoring was carried out in tumor cells but does not predict response to therapy with targeted inhibitors.

+ ROS1 by Immunohistochemistry
  + ___ Negative#
  + ___ Positive##
  + ___ Equivocal### (explain): __________________________

# Absence of ROS1 protein expression in cancer cells suggests that this tumor is unlikely to harbor ROS1 rearrangement and to respond to treatment with a targeted inhibitor, such as crizotinib.

## ROS1 protein expression in cancer cells is highly sensitive for a rearrangement involving ROS1 but is not entirely specific. Therefore, confirmatory molecular methods should be used when ROS1 protein expression is detected.

### Tumors with faint cytoplasmic labeling should be designated as equivocal. This result can rarely occur both with and without mutation.

+ RET Rearrangement by Molecular Methods (Note C)
  + ___ No rearrangement detected#
  + ___ Rearrangement identified##
  + ___ Cannot be determined (explain): __________________________

+ Polysomy:
  + ___ Present###
  + ___ Absent

# Absence of RET rearrangement in cancer cells suggests that this tumor is unlikely to respond to treatment with a targeted RET inhibitor.

## RET rearrangement is associated with response to targeted RET inhibitor therapies, such as cabozantinib and vandetanib.

### Polysomy involving the RET locus confirms that fluorescence in situ hybridization (FISH) scoring was carried out in tumor cells but does not predict response to therapy with targeted inhibitors.

+ KRAS Mutational Analysis
  + ___ No mutation detected
  + ___ Mutation(s) identified" (select all that apply)
    + Codon 12
      + ___ Gly12Cys (GGT>TGT)
      + ___ Gly12Asp (GGT>GAT)
      + ___ Gly12Val (GGT>GTT)
      + ___ Gly12Ser (GGT>GTC)
      + ___ Specific codon 12 mutation not stated
      + ___ Other codon 12 mutation (specify): __________________________

Explanatory Notes

Background
Over half of lung adenocarcinomas contain one of a number of identifiable genetic alterations; some of these can be targeted by a specific therapeutic inhibitor that is either approved by the Food and Drug Administration (FDA) or in clinical trials. The National Comprehensive Cancer Network (NCCN) recommends testing for EGFR mutations and ALK rearrangements in all patients with recurrent or metastatic lung adenocarcinomas in order to guide therapy. The College of American Pathologists (CAP), International Association for the Study of Lung Cancer (IASLC), and Association for Molecular Pathology (AMP) have prepared a joint guideline that provides a detailed description of the patient and specimen requirements and acceptable testing designs and strategies for the detection of these alterations; the reader is referred to this guideline for details that are beyond the scope of this document.

Briefly, approximately 20% of lung adenocarcinomas contain an EGFR activating mutation that predicts response to therapy with EGFR tyrosine kinase inhibitors such as erlotinib. Up to 90% of EGFR mutations occur in two hot spots within the kinase domain, as small deletions in the LREA motif of exon 19 or as a leucine to arginine substitution at amino acid 858 (exon 21). Molecular testing (sequencing or PCR-based approaches) is recommended for EGFR mutation detection whenever possible. Immunohistochemistry (IHC) with EGFR mutation-specific antibodies has high specificity, but suboptimal sensitivity: 76% for EGFR L858R and 60% or less for EGFR exon 19 deletions. In addition, these antibodies do not detect less common types of sensitizing EGFR mutations. In particular, EGFR exon 19 deletion antibody recognizes primarily a 15-base-pair deletion (E746_A750del), which comprises ~50% of exon 19 deletions, but inconsistently detects other types of exon 19 deletions. Because of suboptimal sensitivity, IHC for EGFR mutations may only have a role in situations in which molecular testing is not available or a sample is insufficient or technically unsuitable for testing, such as due to decalcification. If performed, a note should be included that a negative result does not exclude the possibility of EGFR mutations, and testing with molecular methods should be performed if a suitable sample becomes available.

The vast majority of patients with EGFR-mutated lung adenocarcinoma treated with EGFR tyrosine kinase inhibitors will relapse as a result of resistance to these drugs. The most common resistance mechanism is acquisition of the EGFR exon 20 T790M mutation. However, new covalent inhibitors have shown efficacy against relapsed lung adenocarcinomas with EGFR T790M mutations in large phase 2 clinical trials but appear less effective in tumors with alternative resistance mechanisms. Therefore, biopsy at the time of relapse may be required to determine the best course of therapy.

Approximately 5% of lung adenocarcinomas have a chromosomal rearrangement involving the ALK gene, most commonly in the form of an intrachromosomal inversion leading to the EML4-ALK fusion product associated with ALK protein overexpression. Patients with this tumor type are responsive to therapy with ALK tyrosine kinase inhibitors, such as crizotinib. Fluorescence in situ hybridization (FISH) using break-apart probes is currently considered the “gold standard” for detection of ALK rearrangement, which may manifest as separation of the 5' and 3' FISH probes or as deletion of 5' probe. Although both types of alterations are associated with response to ALK-targeted therapies, some studies suggest that 5' probe deletion can rarely represent a false positive FISH result. Detection of ALK protein overexpression by IHC using the 5A4 or D5F3 clones is highly sensitive and specific for an ALK gene rearrangement in lung adenocarcinoma, and the FDA has approved the use of the Ventana ALK (D5F3) CDx Assay as a companion diagnostic for crizotinib. According to the current guidelines, other carefully-validated, but non-FDA approved, ALK immunohistochemistry assays may also be used to screen for ALK rearrangement with confirmation by FISH before initiating ALK-targeted therapy.

Patients receiving ALK-targeted inhibitors inevitably acquire resistance to these drugs, often in the form of ALK kinase domain mutations. The more potent ALK inhibitor ceritinib has shown efficacy in these relapsed patients and has been approved for those who developed resistance to, or could not tolerate, crizotinib. The mechanism of resistance does not clearly predict response to this next line therapy; therefore, the role for rebiopsy in patients with ALK-rearranged tumors is not clear.
ROS1 rearrangement occurs in 1% to 2% of non-small cell lung carcinomas and predicts response to crizotinib therapy. ROS1 fusion partners include SLC34A2, CD74, TPM3, GOPC (FIG), SDC4, EZR, LRIG3, KDELIR2, and CCDC6. Several methods, including FISH, IHC, anchored multiplex or reverse-transcriptase PCR, and next-generation sequencing, may be considered for ROS1 rearrangement detection; no “gold standard” method has been defined. Notably, IHC using the available D4D6 antibody appears to be a robust screening tool, but due to suboptimal specificity, positive results should be confirmed by another technique.

Currently, no targeted tyrosine kinase inhibitor therapies are specifically approved for KRAS mutations. However, KRAS testing is often performed in lung adenocarcinomas because (1) KRAS mutations are typically mutually exclusive with EGFR and ALK alterations, (2) KRAS mutations are the most common oncogenic alteration in lung adenocarcinoma (~20% to 30% of tumors), and (3) KRAS mutation testing is typically quicker, easier, and less costly than testing for EGFR and ALK. Therefore, KRAS mutation analysis may be used in a molecular testing algorithm to eliminate the need for other more costly and time-intensive testing.

BRAF mutations are detected in about 5% of lung adenocarcinomas; V600E mutations comprise approximately half of these and are therefore found in 2% to 3% of tumors. The role of BRAF as a targetable oncogene was recently established in phase II clinical trials combining the BRAF inhibitor dabrafenib with the MEK inhibitor trametinib, where this drug combination was associated with a 63% overall response rate in patients with BRAF V600E-mutated non-small cell lung carcinoma.

The utility of BRAF V600E mutation-specific IHC is not well established in lung adenocarcinoma. The variable sensitivity and specificity of this immunohistochemistry assay relative to mutation analysis reported in other tumor types suggests it may not be appropriate as a clinical tool for BRAF V600E detection in lung tumors.

MET has been recognized as a putative biomarker in lung adenocarcinoma for many years, with amplification implicated as a mechanism of resistance to EGFR inhibitors. In rare cases, de novo MET amplification has been associated with profound responses to therapy with crizotinib. Recently, splicing variants and insertion-deletion mutations leading to MET exon 14 deletion have been found in about 3% of lung adenocarcinomas; these events lead to MET activation and are associated with response to crizotinib and cabozantinib. MET amplification can be seen in tumors with MET exon 14 deletion. MET protein overexpression appears to correlate with MET amplification, although MET immunohistochemistry is controversial as a biomarker for MET-targeted therapies.

Oncogenic RET gene rearrangements have been reported in 1% to 2% of lung adenocarcinoma and are more common in never-smokers. Due to the relative rarity of RET-rearranged tumors, phase 3 clinical trials with targeted agents for RET have not been conducted yet, but preliminary data from phase 2 trials of a multi-targeted inhibitor cabozantinib in RET-rearranged lung tumors are promising. RET rearrangements are detectable by FISH; however, the most commonly described rearrangement, KIF5B-RET, is a product of small intrachromosomal inversion leading to only a subtle split in the FISH probe signals. Thus, the rearrangement could be difficult to detect in practice. Alternative detection methods such as anchored multiplex PCR or next generation sequencing may be useful. The role of RET IHC in predicting RET rearrangements has not been well evaluated.

Lung adenocarcinomas contain a number of other less common alterations that may lead to treatment with targeted inhibitors but have not yet been studied in large controlled trials nor emerged as standard of care. ERBB2 exon 20 insertion mutations are established as oncogenic alterations in lung adenocarcinoma; patients whose tumors harbor these mutations have shown response to HER-tyrosine kinase inhibitors in phase I studies. Alterations in MAP2K1 (MEK1) are rare (<1% of lung adenocarcinoma) but are highly correlated with a smoking history and may predict sensitivity to MEK inhibitors. Alterations leading to PI3K pathway activation, including PIK3CA or AKT1 activating mutations or PTEN loss of function may serve as biomarkers for enrollment in PI3K- or AKT-inhibitor trials. Recently identified fusion events involving NRG1 and NTRK1 (TRKA) appear to be rare but distinctive oncogenic events in a subset of lung adenocarcinomas.

Monoclonal antibodies targeting the programmed death-1 receptor (PD-1) (nivolumab [Opdivo] and pembrolizumab [Keytruda]) and its ligand, PD-L1 (atezolizumab [Tecentriq]), are FDA-approved for use in non-small cell lung carcinoma. All three drugs have been approved for use in the second line (after progression on conventional first line therapies) for both lung adenocarcinoma and squamous cell carcinoma, and...
pembrolizumab has also been approved for use in first line therapy for these indications. Within the clinical trials, PD-L1 expression levels by immunohistochemistry tended to correlate with improved responses to both PD-1 and PD-L1 inhibitors, however the detection antibodies used and scoring cutoffs for the tumor cells and immune cells were highly variable for each drug. Only pembrolizumab has been approved together with a companion diagnostic immunohistochemistry assay (PD-L1 IHC 22C3 pharmDx test); patient tumors are required to show PD-L1 expression in at least 50% of tumor cells in the first line setting and at least 1% of tumor cells in the second line. In contrast, nivolumab and atezolizumab were approved with "complementary" diagnostics PD-L1 IHC 28-8 PharmDx and VENTANA PD-L1 (SP142) assays, respectively. Additional immunotherapeutic and combination therapies are expected to receive FDA approval for use in lung cancer in the future, possibly with distinct paired diagnostics. At this point in time, only pembrolizumab therapy requires knowledge of tumor PD-L1 status. National Comprehensive Cancer Network guidelines currently recommend standard PD-L1 IHC testing in all advanced (stage IIIB and IV) lung squamous cell carcinomas and adenocarcinomas for selection of front line pembrolizumab therapy. At the same time, knowledge of EGFR mutation and ALK rearrangement status is also required, because alterations in these genes predict inferior response to immunotherapies.

A. Suboptimal Specimen Definition
Suboptimal specimens may be defined as those with:
• Improper fixation (see fixation guidelines below).
• Low tumor content, as defined by the molecular diagnostics laboratory. The cutoff for acceptable tumor content depends on the method used by the laboratory. Samples with tumor content below the recommended cutoff may be falsely negative and should be reported as indeterminate if no mutations are detected.

B. Other Mutations
Other mutations include uncommon variants including exon 19 insertions or other missense variants in the kinase domain of EGFR (exons 18-21) that are not listed above. Silent mutations that are known, common, single nucleotide polymorphisms in the general population do not need to be included here.

C. Polysomy
Polysomy (multiple copies) at the ALK, RET, and ROS1 loci may be seen in lung adenocarcinoma and when present confirms that FISH has been performed in a tumor cell population. Current evidence suggests that it does not, however, predict response/resistance to targeted therapies.

D. Other Markers Tested
“Other Markers Tested” should be used to report results from molecular assays not included here that may be relevant to lung cancer therapy. These assays may include, but are not limited to, detection of mutations in genes such as BRAF, ERBB2, and PIK3CA; rearrangements involving ROS1 and RET genes; and MET copy number changes (see “Background” section above).

E. Testing Method for Other Markers
This section should be completed if the “Other Markers Tested” section is filled out and should describe the type of analyses performed for alterations in genes other than EGFR, ALK, and KRAS, as detailed in note D.

F. Fixation
Improper fixation can fail to obtain results with PCR/sequencing-based assays or FISH. Common problems include the following:
• Procedures or fixation involving acid (eg, decalcification, Bouin’s) may degrade DNA.
• Fixation with heavy metals (eg, Zenker’s, B5, B+, zinc formalin) inhibit the enzymes used in PCR.
• Underfixation or overfixation. Fixation for at least 8 hours and less than 72 hours in buffered formalin is recommended; prolonged fixation, particularly in unbuffered formalin, degrades DNA.
